Visual acuity (VA) and hyperacuity (HA) thresholds were measured using a crossed polarity single spatial frequency frequency-doubling-stereo (SR) vision display. Observers compared mean luminance for which monocular SR patterns were invisible (VH threshold), or for which the virtual edge was invisible (VA threshold), with luminance thresholds for distant versus near visual fields. VH thresholds were found to be similar to, or slightly better than, VA thresholds. VA and VH for the first spatial frequency were found to be independently related to stimulus parameters that effectively controlled VA. Although peripheral spatial frequency and mean luminance thresholds were approximately equally sensitive as VA and VH, all measures were substantially more sensitive than the VA as expected for a measure of monocular relative hyperacuity. The finding that VA and VH are not directly related to contrast sensitivity (CS) appears to offer some insight into the disparities in VA and VH results obtained using different methods. The most plausible interpretations of the data are that (a) VA and VH are under some degree of neural/cortical interactions that affect both contrast sensitivity and relative hyperacuity, and (b) that CS is not correlated with VA and VH over a wide range of spatial frequencies. Relative hyperacuity for the cross-cylinder disparities is a useful measure in its own right that could be used to compare the results of different tests for VA and VH.
